## I. EXPLANATION

## 1. PROPORTIONATELY SMALL SAMPLES

These Tables have been specially constructed for practical use in sanitary, pathological and clinical work.

Suppose that we are studying things of any nature, such for cxample as men, cases of sickness, insects, leucocytes, trypanosomes, seeds, stones, etc., and wish to ascertain what proportion of all of them belong to a particular class, that is, have a given characteristic. Then we can answer this qu.estion with absolute certainty only in one way, namely, by examining the whole number of such things that exist in the region under consideration. But this is generally impossible; and we must, therefore, content ourself with examining only as many of the things as we can-ascertaining what proportion of these possess the given characteristic, and thence inferring what probable proportion of the same things in the region under consideration belong to the same class.

[^0]For example, if we wish to know with certainty how many people of any nationality have blue eyes, then we must examine all the people of that nationality. But this will be impossible. Hence we must examine 10 or 100 , or 1,000 or more of the people; ascertain how many of these have blue eyes; and then infer from this sample what proportion of the whole ration are likely to have them.

Everyone knows, of course, that (provided the methods of examination are always equally careful and.trustworthy) our estimate is more likely to be near the truth if we examina large sample than if we examine only a small one--that is. if we examin many of the things than if we examine only a few. For instance, it "ould be absurd to attempt to estimate the proportion of persons with blueyes by examining only five or ten persons. We should come nearer'hy examining one hundred or one thousand, and so on; but we shoulic reach absolute certainty only by examining all the people in the country. The important question now arises: How many of the things must we examine in order to become reasonably sure that our result is within a given percentage of the exact truth? The labours of mathematicians enable us to answer this question, and the following Tables enable us to answer it in most cases without calculation. We must begin by dealing with the case in which the total number of things is so large that we cannot take for a sample more than a very small proportion of that total number. Hence the heading of this section is Proportionately Small Samples.

First, however, we must understand what exactly we mean by the phrases 'reasonably sure' and 'a given percentage of the truth.' Both these phrases contain ideas of degree. Thus, if we are carrying out a strict scientific enquiry, we may wish to be able to say that the betting (or probability, as it is called) is 99,999 to I that our result is within one per cent. of the truth. We must then consult Table A I, under the second column. Or it may suffice to say that the betting is 99,999 to I that our result is within five per cent. of the truth; and we then consult the same table under the sixth column. But it may happen that we can afford to be content with a lower degree of probability than this-it may suffice to say that the betting is only 99 to I that our result is within 3 per cent. of the truth; and we then look at Table A 4, under the fourth column. Lastly, we may be allowed to content ourself with an 'even chance' or
'toss up'-that is, a probability of 1 to 1 ; and for this we consult Table A 6.

The reader will now be easily able to understand the tables. The figures in the heading of each give the degree of sureness (so to speak) with which we may rely upon the inferences drawn from the table. Thus the odds are 99,999 to 1 that the inferences to be drawn from the first table are sound; or, in other words, out of 100,000 trials of the table only one is likely to be wrong. Table A 5 , however, is likely to be wrong once in ten trials; and Table A 6, once in two.

The percentages at the head of each column give the percentage of 'statistical error' - that is, the amount by which the truth is likely to diverge from our observed result. Thus, if our result is 70 per cent., and the statistical error is 5 per cent., then the odds (as denoted by the figures 99,999 to 1 , etc.) are that the truth will lie anywhere between $70+5$ per cent. and $70-5$ per cent.-that is, between 75 per cent. and 65 per cent. If, however, the statistical error is only one per cent., then the truth is likely to lie between the narrower limits, 7 I per cent. and 69 per cent. If the observed result, plus the error, exceeds 100 , or if the observed result, minus the error, is less than $o$, we conclude that the number of things hitherto examined is not yet large enough to yield a useful result.

The figures down the first (left hand) column of each table refer to the percentage of the observed result up to 50 per cent. ; and the figures on the same line in the body of the table give the total number of things which must be examined in order to ensure that that result will lie within the percentage of error given at the head of the corresponding column, with the degree of probability given at the head of each table. Thus, if the observed result is 43 per cent., we must examine 47,780 things to ensure that the odds are 99,999 to I that the truth lies between 44 per cent. and 42 per cent. But we need examine only 1,328 things to ensure that the betting is 99,999 to 1 that the truth lies between 49 per cent. and 37 per cent. We must examine 26,54 I things to ensure, with a probability of 999 to 1 , that the truth lies between 44 per cent. and 42 per cent. (Table A 3 ); but we need examine only 415 things to ensure, with a probability of 9 to 1 , that the truth lies between 47 per cent. and 39 per cent. (Table A 5) ; and only 185 things that, with a probability of 9 to r , it lies between 49 per cent. and 37 per cent.

If the observed percentage is over 50, we subtract it from 100 and obtain the required figures for the remainder. For example, the figures for observed percentages of 70 per cent., 79 per cent., and 85 per cent. are precisely the same as those for 30 per cent., 21 per cent. and 15 per cent.

On inspecting the tables we see at once that the figures diminish rapidly in successive tables, and also in successive columns (from left to right). From these observations we gather, as we might have expected, that the number of things required to be examined diminishes (a) with reduced probability of correctness, and (b) with increased statistical error.

The figures increase as we descend the columns. That is, the number of things required to be examined increases as the observed percentage rises from I per cent. to 50 per cent. ; but after that (by the rule just given) it diminishes as the observed percentage continues to rise from 50 per cent. to 100 per cent.

The tables are calculated for only six degrees of statistical error, namely, from I per cent. to 6 per cent. But it is easy to obtain the figures for any required degree, simply by dividing those in the column for 1 per cent. error by the square of the required degree. Thus for a probability of 99,999 to 1 , and an observed percentage of 43, we must examine 478 things for a statistical error of 10 per cent., and $4,778,000$ things for a statistical error of I-IOth per cent. It will be seen that the columns for 2 per cent., 3 per cent., etc., follow this rule.

It is also easy to obtain approximately the figures for fractional observed percentages, such as 2.5 per cent., or $27^{\circ} 3$ per cent., because the increase in the number of things required to be examined is, roughly, proportional to the increase of the observed percentage. Subtract the next lower from the next higher figure in the table; multiply the remainder by the decimal fraction, and add the result to the next lower figure. Thus in Table A 1 , in the column for I per cent., the figure opposite 2.5 per cent. observed percentage will be about 4,747 ; and opposite 273 per cent. will be about 38,686 . But such refinements will rarely be needed.

We are often obliged to examine such a small number of things that the error is evidently greater than the 6 per cent. calculated for in the Tables, and we may wish to know exactly how much it is. In
this case proceed as follows:- Select the degree of probability required, and in the appropriate table look out the observed percentage actually obtained. Take the number opposite to this in the column for i per cent. error, and divide it by the number of things actually examined. The error will be the square root of the quotient. Thus, suppose that we have examined only 300 leucocytes, and have found 45 per cent. of these to be mononuclears. The number we ought to examine for a I per cent. error at a betting of 9,999 to I is 37,459 . The ratio of this number to 300 is 125 ; and the square root of this is 11.2. Hence the statistical error of our work at this betting is 112 per cent. But 6,697 leucocytes would have sufficed at a betting of only 9 to 1 . The ratio of this to 300 is 2232 ; so that the statistical error at 9 to 1 is only 4.7 per cent.-as could have been roughly inferred from Table A 4 .

The reader should note the large number of things which must be examined before a result can be obtained to any high degree of probability and within narrow limits of error ; and he will doubtless remember many confident assertions based upon much smaller samples.

## EXAMPLES

1. How many persons of one nationality must be examined before we can assure ourselves, to a probability of 99,999 to 1 , that from 65 per cent. to 67 per cent. of all the nation do not possess blue eyes? Answer: 43,744.
2. How many of a patient's leucocytes must be examined before we can bet 999 to I that between 42 per cent. and 40 per cent. of all his leucocytes are mononuclear ?* Answer: 26,194.
3. How many of his leucocytes must be examined before we can bet aboul 100 to I that 69 per cent. to 65 per cent. of all his leucocytes are 'polynuclear'? Anszeer: 3,66S.
4. How many of his leucocytes must be examined before we can bet 9,999 to I that his eosinophile leucocytes number between I' 5 per cent. and 2.5 per cent. of his total leucocytes? Answer: ir,S6S (Muktiply figure in column for 1 per cent. in Table A 2 by 4).
5. On examining 100 of his leucocytes we find that 7 per cent.

[^1]of them are large mononuclears. How many more leucocytes must we examine before betting about 10,000 to I that the same percentage holds for all the leucocytes in his body within an crror of 3 per cent.? Answer: 995.
6. On examining 05 case-records we find that 13 of the patients died. How many more case-records must we examine before betting 99 to I that the case-mortality of the disease is between i9 per cent. and 21 per cent? Auswer: Io,551.
\%. Our new line of treatment has cured one out of five cases of a hitherto incurable disease. How many more cases must we treat before betting 999 to 1 that we can cure between 15 per cent. and 25 per cent. of all cases? Answer: 688.
8. On examining nearly 2,000 of a patient's red corpuscles, we find that 8 per cent. of them are nucleated, and bet 9 to 1 that the percentage of nucleated red-corpuscles in his whole body is -what? Answer: Between 7 per cent. and 9 per cent.

9 On examining 220 things, we find that 31 of them belong to a particular class. What is the statistical error at a probability of 99 to I? Answer: 6 per cent.

Io. On examining 138 leucocytes we find that 15 per cent. of them are large mononuclears. What is the proportion of large mononuclears in the whole body, at a betting of about 1,000 to 1 ? Answer: Anything between 5 per cent. and 25 per cent. (Find the figure for 10 per cent. error.)
II. On examining 500 malaria parasites, we find that it per cent. of them are sexual forms. What is the betting that the statistical error is about I per cent.? Answer: An even chance.
12. In the same case, what is the betting that the error is not greater than 4 per cent.? Auswer: 99 to I.
13. Out of 200 leucocytes we find 23 per cent. to be mononuclears. What is the statistical error at a betting of 999 to I? Answer: $9 ; 9$ per cent. (Square root of $\frac{19178}{200}$ ).
14. Next day, in the same patient, out of the same number of leucocytes, we find 40 per cent. to be mononuclears. What is the statistical error at the same betting? Answer: i1 4 per cent.
15. Can we bet 999 to 1 that there has been an increase of mononuclears in this case? Answer: No, because the errors overlap;
that is, the difference between 23 and 40 is less than the sum of 979 and 114.
16. Can we bet 99 to 1 that there has been an increase? Answer: Yes, because with this lower degree of probability the sum of the errors, namely 7.7 and 8.9 , is less than the difference between the observed percentages, 23 and 40.
17. Working at a probability of 999 to 1 , we find that out of 100 leucocytes two are eosinophiles. What is the error? Answer: Between 4 per cent. and 5 per cent. What are we to conclude? Auswer: That we must examine more leucocytes until the error is at least less than the observed percentage.

I8. On examining 136 things we find about 10 per cent. to belong to a particular class. What, roughly, is the error at a betting of 9,999 to I ? Answer: io per cent. (Find the square root of the quotient of 13,621 divided by 136 .)
19. On examining 200 things we find $\delta 0$ of them belong to a particular class. What is the error at a betting of 99,999 to 1 ? Answer: 153 per cent. (Divide 46,785 by 200, and find the square root of the quotient.)
20. Working at a probability of 9,999 to 1 , and an error of I per cent., how many things must we examine in order to assure an observed percentage of $41 \%$ ? Answer: About 36,789 .

## 1. THE CORRECT PROCEDURE IN PRACTICAL WORK

The Tables will, then, be of practical use in many kinds of sanitary and medical work; as, for instance, in estimating the frequency of death, or of some symptom in a given disease; or of some symptom, such as enlargement of the spleen or rickets, in a population; or in making differential counts of leucocytes in a patient, or of colonies of bacteria growing on a plate culture. But an c.amination of the Tables will convince us that the procedure now generally adopted in attempting such estimates is very faulty, because observers seldom trouble much regarding that all-important point, the size of the sample-that is, the total number of things which they must cxamine in order to obtain a sufficiently correct result. Certainly, often (though not always), they recognise that the sample must be large ; but they usually fix its size quite arbitrarily-as, for instance, when they say beforehand that 200 , or 500 , or 1,000 leucocytes must be
examined for differential counts. This, however, may lead to the most untrustworthy results, because, as we have seen, the size of the required sample is not fixed, but depends on several factors, including the observed percentage of things of the particular classthat is, the very percentage which we are seeking to ascertain. We cannot, therefore, fix the size of the sample beforehand, but must do so as we proceed in the work.

The size of the sample depends upon three factors, namely :
(I) The degree of sureness which we have to attain ;
(2) The percentage of statistical error, or degree of accuracy; which may be allowed; and
(3) The observed percentage of things of the particular class which we are endeavouring to ascertain.

The correct procedure is, therefore, as follows:--
(I) First decide definitely as to the degree of sureness which must be attained, and the percentage of error which may be allowed. These will depend upon the importance of the work and the time which we can devote to it. For strict scientific or large sanitary investigations we may require a very high degree of sureness, say, 99,999 to 1, and very small limits of error, say I per cent. And this will be specially the case when we have to compare resulis obtained at different times; as, for instance, when we wish to know whether the mononuclear leucocytes increase with the progress of a disease (see examples 3 3-I6), or whether an epidemic is diminishing. Here it is absolutely essential that the statistical errors obtained at the two different times are not large enough to overlap. On the other hand, we may often be permitted to adopt lower degrees of sureness and high percentages of error, especially when we are merely seeking some corroborative evidence or when differences between successive estimates are so large and striking that even a large percentage of error cannot mislead the judgment. Here, as in regard to the following paragraph, we must often be guided by the progress of the work. But, as soon as we decide upon these points, we can determine which table, and which column in that table, are to be used.
(2) Secondly, before fixing upon the size of the sample, we should endeavour to obtain by trial a rough estimate of the observed percentage of things of the particular class which we are studying.

Suppose, for example, that we have to make a differential count of leucocytes. Then we do not wish, on the one hand, to allow too much statistical error, or, on the other hand, to waste time over cxamining too large a sample. Suppose, first, that the 9 to I Table is sufficient. Begin by examining ioo leucocytes. Suppose that to per cent. of these are mononuclears. Then we can see at once from the Table how many leucocytes must be examined to give a reliable result at that observed percentage. If a 6 per cent. error will suffice, we anticipate that we shall require to examine only $S_{1}$ more leucocytes. If a 2 per cent. crror must be obtained we shall have to examine $1,52+$ more leucocytes. As we now proceed in the task we shall find that the observed percentage changes considerably when we have examined 200,300 , 400 leucocytes, and so on (we should calculate the percentage, not for each successive batch of 100 leucocytes, but for the total number cxamined from the beginning). Finally, when about 1,400 lencocytes have been examined, we anticipate that we are approaching the required limit (for 2 per cent. error). Suppose that at 1,559 leucocytes the observed percentage stands at just about 36 per cent.-thus agreeing with the Table. We then stop; having obtained a 36 per cent. ratio, with a betting of 9 to $I$, and a statistical error of 2 per cent. That is, the probability is 9 to 1 that the truth lies between 38 per cent and $3 t$ per cent.; and we have not wasted time in reaching this result.

If, however, we require high degrees of probability, or low degrees of error, or both, there will be little use in attempting the preliminary rough estimate by a small sample of only 100 leucocytes, and wc had better take for it at once 500 or 1,000 or more as the case might be.
(3) Of course, in differential leucocyte counts we often possess beforehand some inkling of what observed percentage we are to expect. Thus, the eosinophiles are generally few in number, and the 'polynuclears' numerous; and we judge roughly regarding the size of the sample accordingly. The same thing usually happeus in other kinds of enquiry.
(4) It is a great mistake to suppose that a large sample will compensate for inaccurate working. These Tables are based on the supposition that each thing examined has been accurately assigned to its proper class. Things which camot be certainly
assigned to their proper class must be rejected; but the number of them must be noted, and the proportion which they bear to the whole number of things must be afterwards determined, with estimates of probability and error, by precisely the same methods as those described. They constitute, in fact, a third class by themselves.
(5) If the things under study can be divided into three or more classes, determine separately the proportion of each class to the whole. This does not necessarily require different series of investigations. We simply extract the figures from the records; but care must be taken that the samples are sufficient for each class by itself.
(6) If while examining successive samples of things (such as leucocytes) we find that the observed percentage in each sample in succession tends always in one direction, that is, either to increase or to decrease, then we may suspect that some influence other than mere chance is at work. The number of successive samples required to verify such a suspicion will depend upon the nature of the material, and might be large ; but in many cases if the observed percentage always increases, or always diminishes, in at least five successive samples, then we may have grounds for further enquiry upon the point, or for reference to a trained statistician.
( 7 ) The probability or degree of betting which is generally accepted by statisticians as amounting almost to certainty is 49,999 to I . The figures for this can be obtained by multiplying the corresponding figures for a betting of 9,999 to 1 (Table A 2) by the factor 1189 ; or, what is nearly the same thing, by increasing the figures in Table A 2, by 20 per cent.
(8) Great care must always be taken that samples are chosen really at random, and are not selected with any conscious or subconscious bias.

## 3. PROPORTIONATELY LARGE SAMPLES

We have hitherto dealt with Comparatively Suall Samples-that is, with samples which are small compared with the total number of the things in existence. For instance, if we are studying all the people in a country or all the leucocytes in a patient's body, we shall seldom be able to examine more than a very small proportion of
these people or leucocytes. But there are cases when the total number of things is not so very large that we cannot examine a very considerable proportion of them. Suppose, for instance, that we wish to ascertain the proportion of children with enlarged spleen, not in the whole world, but in a large village ; and suppose that there are 200 children in the village, but that we have time to examine only 50 of them. Here the sample is comparatively large, being one quarter of all the children in the village. Or suppose that we can examine 180 of the children; here the sample is so large that it approaches the whole number of things under study (i.e., the children in the village). Obviously, on examining these large samples we shall approach much nearer to the exact truth than would be anticipated from the Tables. In the second case, for instance, we should have to examine only 20 more of the children in order to obtain absolute certainty (provided that the examinations are careful enough). Hence, clearly, the Tables must be corrected for the case of Large Samples. A very suitable and easily applicable method for this purpose is to multiply the statistical crror given in the Tables by the Factor.

$$
\sqrt{1}-\frac{n-1}{N-1}
$$

where $n$ is the number of things in the sample, and $I$ is the total number of things under study.

Examining this Correction Factor, we see that when $n$ is very small compared with $N$, the term $\frac{n-1}{N-1}$ becomes so small that it may be neglected; so that the Factor now becomes the square root of unity ; that is, unity. This multiplied into the statistical errors given in the Tables does not modify them at all-so that the Tables are then quite correct. Here we have, of course, the case of Comparatively Small Samples, where $N$ is a very large number, such as all the people in a country or all the leucocytes in a person.

Again, if $u=N$, that is, when the sample includes all the things in existence, the term $\frac{n-1}{N-1}$ equals unity, and the Factor becomes zero. This multiplied into the statistical errors makes them vanish. In other words, there is no statistical error because we have reached certainty.

Between these values the Factor is a vulgar fraction, which call
easily be calculated. Thus, if $n=50$ and $N^{\prime}=200$, the Factor is the square root of $\frac{150}{199}$ : that is, 0.868 . This reduces the statistical crror, but not much. If $n=180$, the Factor is the square root of $\frac{20}{199}$ : that is, 0.317 -which reduces them considerably.

If the total number of things is at all considerable--say over 20 then the Factor becomes nearly the same as the square root of I $\frac{n}{N}$. In this case we can give a table of the various values of the Factor which correspond to the various values of $n$. In the following Table the proportion of things examined to total things, $\frac{n}{N}$, is given in percentages, and the corresponding values of the Factor are put below:

|  | Table |  |  |  |  |  |  |  |  | 11 |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $100 \frac{n}{N}$ | $=$ | 5 | 10 | 15 | 20 | 25 | 30 | 35 | 40 | 45 | 50 |
| Factor | $=$ | 0.97 | 0.95 | 0.92 | 0.89 | 0.87 | $0.8+$ | 0.81 | 0.77 | $0.7+$ | 0.71 |
| $100 \frac{n}{N}$ | $=$ | 55 | 60 | 65 | 70 | 75 | 80 | 85 | 90 | 95 | 100 |
| Iactor | $=$ | 0.67 | 0.63 | 0.59 | 0.55 | 0.50 | 0.45 | 0.39 | 0.32 | 0.22 | 0.00 |

Thus, if we examine half the total things, the statistical errors are reduced to about seven-tenths of the values given in Tables A . It will be seen that this Factor makes little difference in the statistical error unless the number of things examined is more than one-tenth of the total.

## EXAMPLES

21. Nine out of 145 children in a village are absent. On examining the remainder we find 14 (say 10 per cent.) of them with enlarged spleen. What is the error at a betting of 9,999 to I ? Answer: 2.5 per cent. (The Factor is I/4. See also Example I8.)
22. There are 1,000 people on an island. Out of 100 of these 60 are found to be affected with filariasis. What is the statistical error at a betting of 9 to I? Anszver: About $7 \cdot 7$ per cent.
23. Out of 884 people in a town, three-quarters are examined, and 73 of these are found to be in bad health. How many of all the people in the town are likely to be unwell? Answer: Between 9 per cent. and 13 per cent., at a betting of 999 to 1 .

## 4. THE NUMBER OF THINGS OF ONE CLASS EXISTING IN A GIVEN AREA, BULK, OR TIME

Suppose that we wish to know the number of things of one kind contained in a given area, bulk, or time. Then the only way to ascertain this with certainty is to count all the things. Suppose, however, that we have no time for this, and must content ourself with counting the things in a measured sample, and then estimating from this observed result the most probable number of the things in the whole area, bulk or time. The question then arises: How large must the sample be in order to reduce the statistical error, with a given degree of probability, to below a given percentage?

For example, suppose that we wish to know how many separate stones there are in a million cubic feet of gravel. We cannot count them all, and must, therefore, content ourself with counting how many there are in a sample of, say, one, two or more cubic feet. In how many cubic feet, then, must we count the separate stones in order to be able to calculate the total with the required degree of accuracy? Or suppose that we wish to know how many leucocytes or parasites there are in the total blood of a patient, then in how much of his blood must we count these objects in order that the most probable truth will lie between sufficiently narrow limits? Shall we take one, two, or more cubic millimetres of his blood for our sample?

First, in order to use the sampling method at all, we must know that the things are equally distributed throughout the area, bulk, or time. If this is not the case, we camot know that our sample accurately represents the whole material. For example, it would be useless to attempt to estimate the population of Britain iy counting all the people in one-tenth of the areal of the country because the population is not distributed equally at random everywhere, but is gathered specially into certain districts and cities according to certain economic laws. Similarly; we cannot estimate by taking samples of the peripheral blond how many blood parasites there are in the whole body muless we know that these organioms do not collect specially in certain parts of the circulation.

But--it may be asked if the things are equably distributed, what further trouble will there be? We have only to count the
number found in any sample, and then to multiply that figure by the total number of samples contained in the whole area, bulk, or time. If the stones are equally distributed in a million cubic feet of gravel, then there will be exactly a million times as many in the whole mass of gravel as there are in one cubic foot. But this is not so. It may be that by chance the stones in the first cubic foot taken as a sample are exceptionally large, and therefore are exceptionally few. Or it may happen by chance that the trypanosomes in a first sample of blood are exceptionally numerous, or exceptionally few, as the case may be. We shall then form a totally wrong estimate if we trust merely to the simple but untruthful method just mentioned.

To obtain accurate estimates by any method in cases like these may require the services of a trained statistician, and also, often, a special study of the kind of material under considerationespecially to ascertain whether the things are really equably distributed. But for the purposes of this Article the following Table will often be useful, because it serves to give some idea of the number of things which must actually be counted if they are equably distributed throughout the whole area, bulk, or time.

Table C

| Probability | Statistical Errors |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | \% | $2 \%$ | $3 \%$ | $4 \%$ | 5\% | $10 \%$ | 20\% |
| 1 to I | 4.550 | 1,13 ${ }^{\text {S }}$ | 506 | 285 | 182 | $+6$ | 11 |
| 9 to I | 27,057 | 6.764 | 3,006 | 1,691 | 1,OS2 | 271 | 68 |
| 99 to 1 | 66,350 | 16.588 | 7.372 | 4,147 | 2,654 | 664 | 166 |

| 9,999 to I | 151,338 | 37,835 | 16,815 | 9,459 | 6,053 | 1,513 | $37^{8}$ |
| 99,999 to 1 | 194,938 | 48,735 | 21,660 | 12,184 | 7,797 | 1,949 | 487 |

Suppose, for example, that a cubic foot of gravel has been found to contain 3,006 stones, then the most probable number of stones in a million cubic feet of the same gravel will be 3,006 millions, within an error of 3 per cent., and at a betting of 9 to 1 ; that is, we may
bet 9 to 1 that the most probable total number of stones in the million cubic feet will lie between about 3,096 and 2,916 millions. Or suppose that 271 trypanosomes have been found in one cubic millimetre of blood in a patient weighing $6+7 \%+$ kilogrammes ( 142 lbs ., or about 10 stone English), who should contain about $3,000,000 \mathrm{c} . \mathrm{mm}$. of blood altogether; then we may bet 9 to 1 that the most probable number of trypanosomes in the whole of his blood will lie between $894,300,000$ and $731,700,000$ ( 10 per cent. error). And if we have counted 4,200 leucocytes in the c.mm. of blood, we may bet 9,999 to I that his total blood contains between 13,356 and in, $8_{44}$ millions of these cells ( 6 per cent. error).

As stated in Section I (page 350) if we wish to know the number of things to be counted in order to yield an error within more than 5 per cent. we have only to divide the figures under the 1 per cent. column twice over by the required percentage (that is, by the square of the required percentage). Thus, for an error of 10 per cent. we divide by 100 ; and for an error of $3 \mathrm{I}^{\circ} 6$ per cent. We divide by $\mathrm{I}, 000$. For example, if we find 27 malaria crescents in 1 c.mm. of the same patient's blood, we may bet 9 to I that he contains between about 106 and 56 millions of crescents altogether (always provided that they are equably distributed in the blood).

The above Table is only for proportionately small samples, as defined in Section 1 (page 348); that is, for samples which are small compared with the total mass of material. When the sample is more than about one-tenth of the total material we should use the Correction Factor of Section 3 (page 357) for proportionately large samples. Thus, if 1,500 leucocytes have been counted in onequarter c.mm. of blood, and we wish to calculate the number in 1 c.mm., then the error by the above Table is about 10 per cent. at a betting of 9,999 to 1 . But by the Table on page 358 the Correction Factor is 0.87 when $\frac{n}{N}$ equals one-quarter, or 25 per cent. Thus the crror is not 10 per cent., but 87 per cent.; and we may bet 0.999 to 1 that the number of lencocytes in 1 c.mm. of blood is hetween 6,522 and 5,478 . But for the total blood content of $3,000,000 \mathrm{c} . \mathrm{mm}$. the crror of 10 per cent. must be maintained, because the one-quarter c.1nm. is now a 'proportionately small sample.' This gives the number of leucocytes in the whole body as most probably lying between $19,8 \mathrm{~m}$ and $\mathrm{I}(1,200$ millions.

We can use the Table in another way. Suppose that we have counted 664 things in a sample. Then the error is 10 per cent. on a probability of 99 to 1 . Hence we can bet 99 to I that all counts in future samples of the same size will lie between $730^{\circ} 4$ and $597^{\circ} 6$ assuming that the sample is proportionately small. This way of stating the case avoids the necessity of determining exactly the size of the sample compared to the whole material. In blood counts, for instance, we are concerned with the number of things in unit of blood rather than in the whole body, and we often wish to know whether this number is increasing or diminishing. If the number of things in a second sample is outside the limits of error declared from the first sample, we may assume, at the appropriate probability, that there has been an increase or decrease, as the case may be. If otherwise, the difference may be due merely to chance in the taking of the samples, and not to any real change in the total number of things in the whole body.

## EXAMPLES

24. We have counted 4,250 red corpuscles in one-thousandth of a cubic millimetre of blood. What is the most probable number in one cubic millimetre, at a betting of 99 to I? Answer: Between about $4,4^{20,000}$ and $4,080,000$.
25. How many may we expect to find in a second sample of the same size, at a betting of 999 to I? Auswer: Between about 4.463 and 4,037 .
26. A week ago we found 490 red corpuscles in one-tenthousandth of a c.mm of a patient's blood. To-day we find only 294 in the same sized sample. May we bet 99,999 to I that there has been a decrease? Answer: No, the errors overlap. May we bet 9 to I that there has been a decrease? Answer: Yes.

27 . Blood has been diluted 100 times. In $\frac{1}{100} t^{\text {th }}$ of c c.mm. of the mixture we found 500 red corpuscles. How many do we expect to find in I c.mm. of the blood at a probability of 999 to I ? Anszer: $5,000,000$, with an error of $14^{\circ} /$ per cent.
28. We have found 553 things in a sample. In how many out of 100 similar samples of the same material should we expect to find an error greater than 7 per cent.? Answer: In ten.
29. A newly-appointed official finds that he is obliged to write

150 letters during his first week of office. How many letters should he expect, at a betting of 999 to I , to have to write at the same rate every week in the future? Answer: 150 , with an error of 26.85 per cent.
30. We have found one filaria embryo in I c.mm. of blood. What may we infer regarding the total number in the whole circulation of $3,000,000 \mathrm{c} . \mathrm{mm}$.? Answer: The odds are 1 to 1 that the error is less than 675 per cent., and that the total number of embryos in the circulation lies between 5,025,000 and 975,000. In one out of two such cases the error may exceed this amount.
